13 **Abstract**

14 The study objective was to compare temporal-spatial and kinetic gait variables in neurologically
15 normal French bulldogs with and without vertebral kyphosis. French bulldogs presented to a
16 dedicated brachycephalic clinic were prospectively enrolled. All dogs underwent general physical,
17 orthopaedic, and neurological examination prior to study inclusion. The presence of vertebral
18 kyphosis was evaluated by computed tomography and kyphosis was defined as a Cobb angle
19 exceeding 10°. Gait variables were collected using a pressure-sensitive GAITRite walkway with
20 GAITFour software and included measurement of total pressure index (TPI) defined as the sum of
21 peak pressure values recorded from each activated sensor by a paw during mat contact.

22 Fifteen French bulldogs with ($n = 8$) and without kyphosis ($n = 7$) were included. Cobb angle in
23 kyphotic dogs ranged from 14.9° to 39.5°. Univariate analyses were initially performed to examine
24 the association between kyphosis and 16 gait variables. When those variables found to be associated
25 ($P < 0.2$) were taken forward into multivariate generalised linear mixed models (accounting for dog,
26 velocity and side), kyphosis had a significant effect upon TPI of the forelimbs and TPI symmetry ratio
27 ($P < 0.05$); however, the size of these effects was small. Although vertebral kyphosis is rarely
28 associated with neurological deficits, it was associated with subtle alterations in kinetic gait variables
29 (TPI forelimbs and TPI symmetry ratio). Further studies are needed to evaluate the clinical
30 importance of altered gait variables in French bulldogs with kyphosis.

32 *Keywords:* Biomechanics; Brachycephalic; Hemivertebra; Spinal

33 **Introduction**

34 Kyphosis is defined as an abnormal dorsal curvature of the vertebral column which is a common
35 sequela to congenital vertebral malformations such as hemivertebra (Guevar et al., 2014, Dewey et al.,
36 2016). Hemivertebra are a common finding in French bulldogs with a reported prevalence of 78% to
37 93.5% in neurologically unaffected animals (Moissonnier et al., 2011, Schlensker and Distl,
38 2013, Ryan et al., 2017). Although vertebral kyphosis can result in neurological abnormalities and
39 spinal cord dysfunction, in most dogs it is not associated with clinical signs and is generally
40 considered an incidental finding on imaging studies of the vertebral column (Moissonnier et al.,
41 2011, Dewey et al., 2016).

42

43 In a small number of dogs however, vertebral kyphosis is directly linked to repetitive and
44 progressive spinal cord injury (Aikawa et al., 2014, Charalambous et al., 2014). This is often
45 multifactorial in nature with dynamic and static factors involved including vertebral instability,
46 vertebral subluxation, and vertebral canal stenosis (Lorenz et al., 2011, Dewey et al., 2016).

47 In addition to neurological dysfunction, kyphosis may also be linked to secondary biomechanical
48 changes of the vertebral column (Faller et al., 2014). This can be manifested as altered gait variables,
49 which are challenging to detect and accurately quantify on visual assessment alone (Carr and Dycus,
50 2016). Pressure-sensitive gait analysis systems provide objective means for assessing gait variables
51 and are a useful tool to improve the ability of clinicians to detect and diagnose subtle gait changes (De
52 Camp, 1997, LeQuang et al., 2009, Carr and Dycus, 2016). Their use for assessment of temporal-
53 spatial gait variables in both human and canine neurological patients has been previously validated
54 (Givon et al., 2009, Gordon-Evans et al., 2009, Lima et al., 2015).

55

56 French bulldogs are predisposed to several spinal conditions including intervertebral disc extrusions
57 (Aikawa et al., 2014, Mayousse et al., 2017). This has been linked to a high prevalence of vertebral
58 malformations in the breed, although the exact pathophysiological mechanisms are currently unknown
59 (Inglez de Souza et al., 2018). Identification and documentation of altered temporal-spatial and kinetic
60 gait variables in French bulldogs with kyphosis may be important to evaluate the full spectrum of
61 potentially important clinical consequences associated with this malformation. Therefore, the study
62 objective was to collect and compare gait variables in French bulldogs with and without vertebral
63 kyphosis by use of a portable pressure-sensitive walkway system. It was hypothesised that vertebral
64 kyphosis in clinically normal French bulldogs would have a significant effect on gait variables
65 compared with French bulldogs without vertebral kyphosis.

66

67 **Materials and methods**

68 *Animals*

69 French bulldogs which presented to a dedicated brachycephalic clinic at the study institution were
70 prospectively enrolled. All dogs underwent general physical, orthopaedic and neurological
71 examination before study enrollment; only those dogs with an unremarkable neurological and
72 orthopaedic examination were included in the study. Radiographic evaluation to further exclude
73 orthopaedic disease was not performed. Clinical information retrieved from the medical records
74 included: signalment, clinical history, physical examination findings, and results of diagnostic
75 investigations including diagnostic imaging findings. The study was granted ethical approval by the
76 Royal Veterinary College Clinical Research Ethical Review Board (Protocol number 20151393;
77 Approval date 21 October 2015). Owners of all dogs were required to sign an informed consent form
78 prior to inclusion (see Appendix: Supplementary File 1).

79 *Gait analysis*

80 Gait variables were collected using a 4.88 × 0.61 m portable walkway (GAITRite, platinum version,
81 CIR Systems) with 16,128 embedded pressure-sensitive sensors. The walkway was connected to a
82 laptop computer with dedicated software (GAITFour software, version 40f, CIR Systems). A camera
83 (Logitech mega pixel web camera, Logitech) was positioned immediately adjacent to the mat at a
84 height of 0.5 m to create digital video files of each pass along the walkway; this was automatically
85 linked to gait data generated from each walkway trial to allow verification of walks and footfall when
86 processing data. Prior to data analysis, paw prints were identified using the software program which
87 replicated gait patterns previously identified by the user.

88

89 The study protocol was based on previously validated gait analysis protocols (Light et al., 2010). Each
90 dog was allowed a habituation period of 10 min, during which they were walked freely around the
91 study area. Dogs were then walked along the mat until three valid trials were obtained within a 30-
92 min period, and only the first three valid trials were selected for study inclusion. A trial was
93 considered valid when the dog walked straight ahead, at a consistent walk, with the head centered
94 straight forward. Three gait cycles per trial were needed as a minimum. The velocity of individual gait
95 cycles was compared to ensure variation within each pass along the walkway did not exceed 10%.
96 Walk velocity was restricted between 0.6 to 1.0 m/s. Those walks which did not meet these criteria
97 were excluded. All dogs were walked by one of two study authors who were experienced animal
98 handlers and trained in the study protocol (SW, HS). Dogs were walked along the mat in both
99 directions equally, and the side which the leash was held alternated between left and right depending
100 on the direction of walk. All walks were completed prior to induction of general anaesthesia and
101 completion of imaging studies.

102

103 *Imaging Studies*

104 The presence of vertebral kyphosis was evaluated based on computed tomography(CT) imaging under
105 general anesthesia, and vertebral kyphosis was defined as a Cobb angle exceeding 10°. CT images
106 were acquired using a 16 multi-detector row unit (Mx8000 IDT, Philips). All imaging studies were
107 assessed using a PACS workstation DICOM viewer (Osirix Imaging Software, version 3.9.2). The
108 degree of vertebral kyphosis was evaluated through measurement of the Cobb angle by one study
109 author (SDD), using the automated method described by Guevar et al. (2014). Study dogs were then
110 divided into kyphotic and non-kyphotic groups.

111 *Gait variables*

112 The following temporal-spatial data were extracted for each dog: (1) Stride length (the distance
113 between two strikes of a single paw on the ground); (2) Stance time (the length of time a paw is in
114 contact with the ground during a gait cycle); (3) Hind reach (calculated from the heel center of the
115 hind paw to the heel center of the fore paw on the same side); (4) Number of activated sensors per
116 paw per gait cycle; (5) Number of gait cycles per trial; and (6) Mean gait velocity. Furthermore, the
117 kinetic variables ‘total pressure index’ (TPI), and TPI % were also determined. TPI was defined as
118 ‘the sum of peak pressure values recorded from each activated sensor by a paw during mat contact,
119 represented by switching levels and reported as a scaled pressure from zero to seven for each sensor’
120 (Light et al., 2010). TPI % represents the TPI as a percentage of all four limbs and illustrates weight
121 distribution across all four paws.

122 *Statistical methods*

123 Data was exported from the gait software into a commercially available data analysis programme
124 (Microsoft Excel 15.26, 2016) for descriptive statistics. Symmetry ratios (SR) of gait variables were
125 calculated for each dog by dividing the forelimb value of each parameter by the hind limb value
126 ($SR = X_{fore}/X_{hind}$). The SR metric was chosen over other measures of symmetry as it has the advantage
127 of being easily interpreted (Patterson et al., 2010).

128

129 Further statistical analysis was performed using SPSS Statistics Desktop (V22.0, IBM) to evaluate the
130 effect of vertebral kyphosis on individual gait variables. Generalised linear mixed models (GLMM)
131 were constructed with individual gait variables included in models as the outcome measures, with
132 presence of kyphosis as a binary predictor variable. Three trials were included for each dog in all
133 analyses, with non-independence of this data accounted for by including dog ID as a random effect in
134 all models. In initial univariate GLMM analyses, the effect of kyphosis upon all individual gait
135 variables was investigated, with only dog ID included as an additional (random) effect. For those gait
136 variables associated with kyphosis at the univariate level ($P < 0.2$), multivariate models were
137 constructed where velocity and side of the dog were included as fixed effects to account for their

138 potential impact upon other gait variables. Correlation between gait variables was checked to reduce
139 the number of variables tested and thus the type I error. $P < 0.05$ was considered statistically
140 significant in all tests.

141

142 To estimate the magnitude of the effect of kyphosis upon gait variables, the omega-squared (ω^2) effect
143 size statistic was calculated for models in which kyphosis was a significant predictor of gait. Omega-
144 squared is an estimate of how much variance in the outcome variables (gait) are accounted for by the
145 explanatory variables (in this case, kyphosis). Magnitude of ω^2 was interpreted in line with Murphy
146 and Myers (2004), where 0 indicates no effect, a small effect = 0.01, a medium effect = 0.06 and a
147 large effect = 0.14.

148

149 **Results**

150 Twenty French bulldogs were initially enrolled in the study. Five dogs were excluded as they failed to
151 produce three valid gait trials within the 30-min period. Hence, 15 French bulldogs were included in
152 the final study. These dogs had a mean age of 21 months (range: 6–48 months) and a mean body mass
153 of 11.2 kg (range: 7.8–15.4 kg). Twelve dogs were male (four neutered) and three were female (one
154 neutered).

155

156 All dogs underwent CT imaging of the cervical and thoracic vertebral column for further investigation
157 of brachycephalic obstructive airway syndrome (BOAS); seven dogs had no vertebral kyphosis while
158 eight dogs had evidence of kyphosis (Fig. 1). Cobb angle in kyphotic dogs ranged from 14.9° to 39.5°
159 (mean: 26.2°). Cobb angle in non-kyphotic dogs ranged from 0.5° to 6.2° (mean: 4.1°). Twelve study
160 dogs had evidence of thoracic vertebral body malformations while only three study dogs had no
161 obvious vertebral malformations. Of those dogs with thoracic vertebral body malformations, one dog
162 had a single malformed vertebral body while the remaining eleven dogs had between 2 and 9
163 malformed vertebrae. The most commonly affected vertebra was the sixth thoracic vertebra (T6),
164 which was abnormal in nine dogs, but affected vertebrae ranged from the second to the thirteenth
165 thoracic vertebra (T2–T13). In those dogs with kyphosis, all vertebral malformations were associated
166 with the kyphotic curve apex.

167

168 Three valid gait trials were collected for each dog at a walk (Table 1). The average number of gait
169 cycles per valid trial was five. Gait velocity was 0.742 m/s (standard deviation (SD) \pm 0.122) for non-
170 kyphotic dogs and 0.793 m/s (SD \pm 0.158) for kyphotic dogs. There was no statistically significant
171 difference in gait velocity between the two groups ($P = 0.241$). In non-kyphotic dogs, the number of
172 activated sensors in the thoracic limbs was 9.83 (SD \pm 1.24) and in kyphotic dogs, it was 9.75
173 (SD \pm 1.48). In non-kyphotic dogs, the number of activated sensors in the pelvic limbs was 5.35

174 (SD \pm 0.71) and in kyphotic dogs was 4.83 (SD \pm 1.47). Overall, there was no significant difference in
175 the number of activated sensors in the thoracic limbs ($P = 0.847$) or pelvic limbs ($P = 0.129$) between
176 kyphotic and non-kyphotic groups.

177

178 In univariate analyses (with dog ID accounted for as a repeated measure), seven gait variables were
179 found to be associated with the presence of kyphosis ($P < 0.20$): Hind reach, TPI forelimbs, TPI %
180 forelimbs, TPI hind limbs, TPI % hind limbs, TPI symmetry ratio, and TPI % symmetry ratio (see
181 Appendix: Supplementary File 2). For non-kyphotic dogs, TPI fore limbs was 66.5 (95% CI: 64.7–
182 68.3) and TPI hind limbs was 33.4 (95% confidence interval (CI): 31.6–35.2). For kyphotic dogs, TPI
183 fore limbs was 69.4 (95% CI: 67.6–71.2) and TPI hind limbs was 30.8 (95% CI: 28.9–32.6). As TPI
184 was strongly correlated with TPI % for fore and hind limbs in kyphotic and non-kyphotic dogs
185 ($r > 0.7$ and $P < 0.001$), only TPI variables were explored in multivariate analyses, to reduce the
186 likelihood of type I errors from multiple testing.

187

188 In multivariate analyses, kyphosis significantly affected two gait variables: TPI forelimbs and TPI
189 symmetry ratio (Fig. 2; see Appendix: Supplementary File 3). Although significant, the effect size of
190 kyphosis upon these two kinetic gait variables was small (TPI fore $\omega^2 = 0.004$; TPI symmetry ratio
191 $\omega^2 = 0.003$). Velocity had a significant effect on TPI forelimbs, TPI hind limbs and TPI symmetry
192 ratio. No effect of side was found in any model ($P > 0.05$).

193

194 **Discussion**

195 Although vertebral kyphosis is rarely associated with neurological deficits, the findings of the current
196 study suggest an association with subtle alterations in kinetic gait variables. Dogs with kyphosis had a
197 greater TPI in their thoracic limbs and an altered TPI symmetry ratio when compared to dogs without
198 kyphosis. This means that dogs with vertebral kyphosis shifted weight from the pelvic limbs onto the
199 thoracic limbs. While the effect of kyphosis was statistically significant, the numerical difference in
200 gait variables between the study groups was relatively minor, and calculated effect sizes were small.
201 The results should therefore be interpreted with the small magnitude of effect in mind. However, the
202 study hypothesis was largely unsupported, as the majority of gait variables tested were not
203 significantly different between kyphotic and non-kyphotic dogs.

204

205 Although the dogs in this study were clinically normal, altered kinetic gait variables which were not
206 evident on visual gait assessment and only detectable using the walkway, suggest that dogs with
207 kyphosis may undergo a compensatory adaption secondary to a structural abnormality. It is unclear if
208 the pathophysiological basis for this compensatory adaption is due to compromise of neurological

209 pathways involving sensory or motor tracts, or if it is simply a biomechanical adaptation. The inability
210 to definitively differentiate between ataxia and paresis using the pressure walkway is an intrinsic
211 limitation of the system. In the human literature, previous studies utilizing the GAITrite system
212 attempted to correlate alterations in temporal-spatial gait variables with functional impairments using
213 a graded scoring system, although all those patients were neurologically abnormal (Givon et al.,
214 2009). Interestingly, in a study by Gordon-Evans et al. (2009), dogs with thoracolumbar spinal cord
215 disease also distributed more weight on neurologically normal thoracic limbs as a result of pelvic limb
216 ataxia compared with clinically normal dogs. In the same study, neurologically affected dogs also
217 exhibited decreased stance time, stride time, and stride length in the thoracic limbs, and increased
218 swing time in the pelvic limbs (Gordon-Evans et al., 2009). In contrast, kyphotic dogs in the current
219 study distributed more weight on thoracic limbs but temporal-spatial gait variables remained
220 unchanged; this suggests the pathophysiology of altered kinetic gait variables in kyphotic dogs may
221 have a non-neurological mechanism and may simply represent a biomechanical adaptation rather than
222 subclinical neurological disease.

223

224 While the clinical relevance of the study findings is currently unclear, vertebral malformations could
225 predispose affected dogs to degenerative changes of the vertebral column. Dogs with kyphosis are
226 more likely to have a different anatomical distribution of thoracolumbar intervertebral disc disease
227 and earlier degeneration of adjacent intervertebral discs (Aikawa et al., 2014, Faller et al.,
228 2014, Inglez de Souza et al., 2018). French bulldogs are known to be at risk of spinal conditions such
229 as intervertebral disc extrusion and spinal arachnoid diverticula (Aikawa et al., 2014, Mauler et al.,
230 2014, Mayousse et al., 2017). The pathophysiology is considered to be multifactorial with genetic,
231 anatomic and biomechanical factors involved (Brisson, 2010, Mauler et al., 2014), but altered gait
232 variables and vertebral loading is one possible cause. The mechanisms responsible are likely related to
233 asymmetrical loading of vertebrae and intervertebral discs adjacent to the kyphotic vertebral
234 segments, and secondary effects on supporting soft tissues with altered stress-loading cycles (Stokes
235 and Iatridis, 2004, Moissonnier et al., 2011, Ortega et al., 2012, Aikawa et al., 2014, Faller et al.,
236 2014). Therefore, while vertebral kyphosis is rarely a direct cause of clinical signs in affected dogs, it
237 is possible that biomechanical changes associated with kyphosis could contribute to the development
238 of spinal conditions such as intervertebral disc disease. Biomechanical changes and chronic alterations
239 in loading of appendicular joints could also have wider implications on the health status of affected
240 individuals, such as increased incidence of orthopaedic disease and degenerative arthropathies of
241 thoracic limbs (Kaplan et al., 2017, Roemhildt et al., 2010, Vos et al., 2009). The study findings
242 suggest that although thoracic vertebral malformations and spinal kyphosis are only rarely considered
243 the direct cause of clinical signs, their occurrence should not necessarily be a benign finding. These
244 conclusions may raise welfare issues associated with the breed conformation and could also have
245 implications for other screw-tailed brachycephalic breeds commonly affected with vertebral kyphosis.

246 Temporal-spatial gait variables have been evaluated in several canine breeds to establish breed-
247 specific reference ranges (Light et al., 2010, Lima et al., 2015). The results from non-kyphotic study
248 dogs provide breed-specific reference values not previously reported for French bulldogs. Gait
249 variables vary significantly between dogs of different body mass and size, which may in turn, lead to
250 variation in the center of gravity and influence the force distribution between different limbs (Bertram
251 et al., 2000, Voss et al., 2010). Although it is difficult to directly compare gait variables between
252 different breeds for the reasons outlined above, comparison of symmetry ratios can be useful. In the
253 current study, non-kyphotic dogs had a 67:33 percentage weight distribution for thoracic and pelvic
254 limbs, respectively. This ratio is noticeably different from the previously reported 60:40 weight
255 distribution assumed for the normal canine population at a walk (Nunamaker and Blauner,
256 1985; Kano et al., 2016). This suggests that this deviation of ‘normal’ is likely breed specific and
257 related to conformational differences between specific canine breeds, as demonstrated in a previous
258 study (Voss et al., 2011).

259

260 The prevalence of thoracic vertebral malformations in our study population was similar to earlier
261 studies (Moissonnier et al., 2011, Schlensker and Distl, 2013, Ryan et al., 2017). The fact that the
262 majority of neurologically normal French bulldogs are affected with such malformations creates some
263 difficulty to define what is ‘normal’ in this breed. It would be interesting to collect gait variables in
264 French bulldogs with neither thoracic vertebral malformations nor kyphosis to better investigate the
265 influence of these anomalies on gait variables. Practically however, this is challenging considering up
266 to 93.5% of French bulldogs may be affected with such malformations (Ryan et al., 2017). Future
267 work involving data stratification based on Cobb angle measurement may focus on the correlation
268 between gait variables and the degree of kyphosis. A vertebral angulation threshold of 10° was chosen
269 in this study as this has previously been reported as clinically relevant in the human literature
270 (Angevine and Deutsch, 2008). While a Cobb angle measurement of 35° or more is linked to an
271 increased risk of neurological disease (Guevar et al., 2014), it is quite plausible that there could be
272 clinical consequences well before this. Vertebral kyphosis has previously been classified as mild
273 (<15°), moderate (15–60°), or severe (>60°) although no direct correlation with clinical significance
274 was reported (Aikawa et al., 2007).

275

276 The primary limitation of the current study was the small sample size which was smaller in number
277 than the number of gait variables examined; this could lead to type II error and restricts the possible
278 conclusions. Nevertheless, two gait variables were significantly different between the study groups
279 and these findings provide a basis for further research which would ideally utilize a larger sample
280 size. The variation in handlers is another limitation; despite both handlers being experienced and
281 trained in the study protocol, there is potential for introduction of variability (Keebaugh et al., 2015).
282 Although previous studies by Gordon-Evans et al. (2009) and Lima et al. (2015) may allow some

283 predictions regarding the possible effect of kyphosis on specific gait variables, this study is one of the
284 first of its kind. Therefore, the study hypothesis was rather exploratory and examined a broad set of
285 gait variables. This restricts the impact of the study conclusions, although the findings provide
286 grounds on which future research hypotheses with a more specific focus may be based. Another
287 limitation was the lack of a ‘control’ group of dogs. It would indeed have been valuable to recruit a
288 population of dogs with neither evidence of vertebral kyphosis or vertebral malformations. Due to the
289 high prevalence of vertebral malformations within the breed (Moissonnier et al., 2011, Schlensker and
290 Distl, 2013, Ryan et al., 2017), this was not practically possible within the time constraints of the
291 study. Finally, another study limitation was the lack of information regarding classification of each
292 vertebral malformation in the dogs under study. While this was beyond the scope of the current study,
293 it is possible that different vertebral malformations may have a different effect on gait variables.

294

295 **Conclusions**

296 Vertebral kyphosis was associated with subtle alterations in kinetic gait variables (TPI fore limbs and
297 TPI symmetry ratio), with kyphotic dogs redistributing weight from pelvic limbs onto thoracic limbs.
298 This could be linked with altered vertebral loading and potentially predispose French bulldogs to
299 degenerative changes of the vertebral column. However, 14 of 16 gait variables tested were not
300 significantly different between kyphotic and non-kyphotic dogs. Therefore, the study hypothesis was
301 largely unsupported. Further studies are necessary to fully evaluate the clinical relevance of altered
302 gait variables and its influence on spinal biomechanics.

404

405 **Table 1.** Descriptive statistics of temporal-spatial gait variables in kyphotic versus non-kyphotic dogs.

Variable	No kyphosis	Kyphosis
Hind reach (m)	0.015 ± 0.044	0.042 ± 0.044
TPI fore	33.24 ± 1.99	34.70 ± 2.14
TPI hind	16.70 ± 1.99	15.38 ± 2.18
TPI symmetry ratio	2.12 (1.67–2.32)	2.28 (1.85–3.09)
TPI fore (%)	66.49 ± 3.98	69.40 ± 4.30
TPI hind (%)	33.41 ± 3.98	30.75 ± 4.36
TPI percentage symmetry ratio	2.06 (1.76–2.25)	2.34 (1.95–2.65)
Stride length fore (m)	0.427 ± 0.053	0.423 ± 0.049
Stride length hind (m)	0.423 ± 0.052	0.421 ± 0.049
Stride length symmetry ratio	1.00 (0.99–1.02)	1.01 (0.99–1.02)
Stance time fore (s)	0.34 ± 0.07	0.31 ± 0.06
Stance time hind (s)	0.28 ± 0.09	0.26 ± 0.06
Stance time hind symmetry ratio	1.15 (1.13–1.35)	1.16 (1.08–1.28)
Stance time fore (%)	57.49 ± 4.48	56.55 ± 4.34
Stance time hind (%)	46.94 ± 8.62	46.60 ± 6.94
Stance time percentage symmetry ratio	1.15 (1.12–1.39)	1.17 (1.09–1.29)

406

407 ^aNormally distributed variables are stated as mean ± standard deviation (SD) and non-normally
 408 distributed variables as median (25th–75th percentiles).

409 ^bTotal pressure index (TPI).

410

411 **Figure 1.** Saggital computed tomography (CT) images of two dogs: (A) is regarded as non-kyphotic
412 and has a Cobb angle of 2.4°; (B) is regarded as kyphotic and has a Cobb angle of 37.5°.

413

414

415

416 **Figure 2.** Graphical illustration of data for total pressure index (TPI) of the forelimbs and the TPI
417 symmetry ratio in kyphotic and non-kyphotic dogs.

418
